

# Monads

## Lecture 12

# Monads

---

- A language without side effects can't do I/O
  - Side effects are critical in some applications
    - For expressiveness and/or efficiency
- Haskell has a general mechanism for side effects and much more
  - based on *monads*

# An Example: A Counter

---

- How do we keep track of the # of times a function  $f$  is called?
- In C: a global (or static) variable `count`
  - `f(x) = { count++; ... body of function ... }`
- In Haskell: an extra parameter to  $f$ 
  - `f :: Int -> Foo -> (Int * Bar)`
  - `f count x = (count+1, ... body of function ...)`

## An Example (Cont.)

---

- Expanding on this program:

$g \text{ count } y = \dots (c,v) = h(\text{count},a) \dots$

$h \text{ count } z = \dots (c,w) = f(\text{count},b) \dots$

$f \text{ count } x = (\text{count}+1, \dots \text{body of function} \dots)$

# A Problem

---

- The functional solution has a problem
- The counter must be maintained by  $f$ 's caller
  - And possibly  $f$ 's caller's caller
  - Or even the entire program
- Passing around the "state" explicitly is painful
  - And poor software engineering

# An Idea

---

- Could we hide the state in a type?
- What does a state transformer do?
  - Maps a state to a new state
  - And (possibly) returns a value

`type StateTrans s a = s -> (s,a)`

# Statements

---

- A *statement* is a state transformer
  - E.g.,  $x = a * b$  in C
- A sequence of statements successively transforms the state

$s1; s2$

- Define a sequencing combinator:  
 $(\gg=) :: \text{StateTrans } s \ a \ \rightarrow (a \ \rightarrow \ \text{StateTrans } s \ b) \ \rightarrow \ \text{StateTrans } s \ b$   
 $(\gg=) \ f \ g \ s0 = \text{let } (s1, v) = f \ s0 \ \text{in } g \ v \ s1$

# Sequencing

---

- Look at this combinator more closely  
 $(\gg=) :: \text{StateTrans } s \ a \rightarrow (a \rightarrow \text{StateTrans } s \ b) \rightarrow \text{StateTrans } s \ b$
- This combinator must evaluate the first state transformer and then the second

# Sequencing (Cont.)

---

- Now expand the type:

$(\gg=) :: \text{StateTrans } s \ a \rightarrow (a \rightarrow \text{StateTrans } s \ b) \rightarrow \text{StateTrans } s \ b$

$(\gg=) :: (s \rightarrow (s,a)) \rightarrow (a \rightarrow (s \rightarrow (s,b))) \rightarrow (s \rightarrow (s,b))$

- Note two things:
  - The manipulation of state is hidden inside the type `StateTrans`
    - If this type is abstract, access to the state is restricted
  - The statements *have not been executed yet*
    - `>>=` is a "script builder"

# Example Revisited

---

- Consider the counter example  
 $f \text{ count } x = (\text{count}+1, \dots \text{body of function } \dots)$
- The state is an integer:  
 $(\gg=) :: \text{StateTrans Int } a \rightarrow (a \rightarrow \text{StateTrans Int } b) \rightarrow \text{StateTrans Int } b$
- We need a state transformer that updates the state:

$++ :: \text{Int} \rightarrow (\text{Int}, ())$   
 $++ \ i = (i+1, ())$

## The Example, Cont.

---

- Consider the counter example

$f \text{ count } x = (\text{count}+1, \dots \text{body of function } \dots)$

- Rewrite:

$f :: \text{Foo} \rightarrow \text{StateTrans Int Bar}$

$f \ x = ++ \gg= \ \_ \dots \text{body of function } \dots$

# The Example, Cont.

---

- This isn't quite right:

$f :: \text{Foo} \rightarrow \text{StateTrans Int Bar}$   
 $f\ x = ++ \gg= \_\dots \text{ body of function } \dots$

- “Body of function” needs to be a state transformer, too!
- Use a new function:

$\text{unit} :: a \rightarrow \text{StateTrans } s\ a$   
 $\text{unit } v\ s = (s, v)$

# The Original Example

---

$g \text{ count } y = \dots (c,v) = h(\text{count},a) \dots$

$h \text{ count } z = \dots (c,w) = f(\text{count},b) \dots$

$f \text{ count } x = (\text{count}+1, \dots \text{body of function} \dots)$

# Rewritten as a State Transformer

---

$g\ y = \text{unit}(\dots) \gg= \_\_.h(a) \gg= \_v.\text{unit}(\dots)$

$h\ z = \text{unit}(\dots) \gg= \_\_.f(b) \gg= \_w.\text{unit}(\dots)$

$f\ x = ++ \gg= \_\_.\text{unit}(\dots \text{ body of function } \dots)$

# Dicussion

---

- The “plumbing” of the state is hidden
  - State only referred to explicitly where needed
  - Just as in C
- The types help
- State still affects global program structure
  - But functional sub-parts are clearly delineated

# Discussion

---

- What is state in a functional world?
- Answer:
  - A hidden "extra" parameter to every function
  - This extra parameter is restricted
    - Cannot be copied
    - Strict sequencing of operations must be observed
- This is what `>>=` does
  - Threads the state using higher-order functions

# Another Example of a State Monad

---

```
data SM a = SM (Int -> (Int,a))
```

```
SM c1 >>= fc2 =
```

```
    SM (\s0 -> let (s1,r) = c1 s0 in fc2 r s1)
```

```
unit k = SM \s -> (s, k)
```

```
a >> b    = a >>= \_ -> b
```

```
read      = SM \s -> (s, s)
```

```
inc       = SM \s -> (s+1,())
```

```
init      = \i.SM \s -> (I,())
```

```
(init 0) >> inc >> read >>= \x -> ... compute with x ...
```

# Observation

---

- Consider the type `StateTrans` again:  
`type StateTrans s a = s -> (s,a)`
- Note that we really used  
`type StateTrans Int a = Int -> (Int,a)`
- The type of the state was fixed
- But the type of computations on state is parameterized by `a`

# Monads

---

A Monad is a type  $M\ a$  with two operations:

$unit :: a \rightarrow (M\ a)$

$bind :: M\ a \rightarrow (a \rightarrow M\ b) \rightarrow M\ b$

And

- $bind$  (or  $\gg=$ ) is associative  
 $(a \gg= \backslash x \rightarrow b\ x) \gg= \backslash y \rightarrow c\ y =$   
 $a \gg= (\backslash x \rightarrow (b\ x \gg= \backslash y \rightarrow c\ y))$
- $unit$  is an identity

# A Critical Distinction

---

- Let  $M$  be a monad
- If  $a$  is a type of *values*
  - E.g.,  $\text{Int}$ ,  $\text{Char}$ ,  $\text{Int} \rightarrow \text{Int}$
- Then  $M a$  is a type of *computations*
  - E.g., State transformers on  $\text{Ints}$

# Monadic Programming

---

- Monads allow one to:
  - Hide "extra" arguments to functions
  - Add primitives to access those hidden values
  - Compositionally build computations
- None of this is specific to state
- There are many other applications

# I/O

---

- **IO** monad provides input/output operations
  - The state is the external world
  - Primitive operations to read/write devices

$IO :: World \rightarrow (World, a)$

- Computations in the **IO** monad map the state of the world to a new world value
  - The world is the state

# I/O Operations

---

$\text{getcIO} :: \text{IO Char}$

$\text{putcIO} :: \text{Char} \rightarrow \text{IO Char}$

$\text{bindIO} :: \text{IO a} \rightarrow (\text{a} \rightarrow \text{IO b}) \rightarrow \text{IO b}$

$\text{unitIO} :: \text{a} \rightarrow \text{IO a}$

## More Useful IO Operations

---

- With IO, we often don't care about the return value, so we can define functions to ignore it

$(\gg) :: IO\ a \rightarrow IO\ b \rightarrow IO\ b$

$(\gg) s1\ s2 = s1 \gg= \_\_.s2$

$doneIO :: () \rightarrow IO\ ()$

$doneIO () = unitIO ()$

# An Example

---

```
echo = getcIO >>= \a ->  
    if (a == eof) then  
        doneIO  
    else  
        putStrLn a >> echo
```

# IO in Haskell

---

- The IO Monad is *the* way to I/O in Haskell
- Programs must have the type `IO a`
  - A whole program is an I/O performing computation
- The `World` values are crucial
  - Explicit in the compiler, like all other values
  - Show the dependencies between computations
  - Ignored by the code generator

# Single-Threadedness

---

- Critical to correctness is that the state (or world) is single threaded
- If a monad is abstract, this is guaranteed
  - Bind/unit are single-threaded
    - Take one reference, produce one reference
  - These are the only operations on the type
- Also used for, e.g., efficient array update

# Non Single-Threadedness

---

- Haskell does have some "dangerous" I/O primitives that are not single-threaded
  - E.g., to do asynchronous I/O
- These may lead to race conditions
  - But that is part of the desired functionality

# Other Uses of Monads

---

- Continuations
  - Hide the continuation in the monad
- Exceptions
  - Special case of continuations
- Passing state backwards
  - How many calls of this function are left in the execution?
  - Just reverse passing of state in `bind`
  - Depends on lazy evaluation

# Composable Interpreters

---

- Make each language feature a monad
- Build an interpreter with exactly the features you want by composing monads
  - Guy Steele's work
- Unfortunately, composing monads doesn't work in general
  - But this is the closest we've gotten to compositional language design

# Conclusions

---

- Monads are a way of structuring programs
- Depend critically on higher-order functions
- A new idea
