Calgary, November 4, 2014
PIMS/Shell Lunchbox Lecture
Shell Calgary Place Tower 1
12:00-1:00 PM
The Basic Problem

Suppose you are saving for retirement (i.e. 20 years away)

- What is your portfolio allocation strategy?
  - i.e. how much should you allocate to bonds, and how much to equities (i.e. an index ETF)

- How should this allocation change through time?
  - Typical rule of thumb: fraction of portfolio in stocks = 100 minus your age.

- Target Date (Lifecycle) funds
  - Automatically adjust the fraction in stocks (risky assets) as time goes on
  - Use a specified “glide path” to determine the risky asset proportion as a function of time to go
  - At the end of 2013, over $600 billion invested in US

\(^1\)Morningstar
Risk-reward tradeoff

This problem (and many others) involve a tradeoff between risk and reward.

Intuitive approach: multi-period mean-variance optimization
- When risk is specified by variance, and reward by expected value
  → Even non-technical managers can understand the tradeoffs and make informed decisions

In this talk, I will determine the optimal asset allocation strategy
- Objective: minimize risk for specified expected gain
- Use tools of optimal stochastic control

\(^2\)I am now a member of the University of Waterloo Pension Committee. I have seen this problem first-hand
Multi-period Mean Variance

Criticism: variance as risk measure penalizes upside as well as downside

I hope to convince you that multi-period mean variance optimization

- Can be modified slightly to be (effectively) a downside risk measure
- Has other good properties: small probability of shortfall

Outcome: optimal strategy for a Target Date Fund

- I will show you that most Target Date Funds being sold in the marketplace use a sub-optimal strategy
“All models are wrong: some are useful”

Let $S$ be the price of an underlying asset (i.e. TSX index).

- A standard model for the evolution of $S$ through time is Geometric Brownian Motion (GBM).
- Basic assumption: price process is **stochastic**, i.e. unpredictable.$^3$

$$\frac{dS}{S} = \mu \, dt + \sigma \phi \sqrt{dt}$$

$\mu =$ drift rate,
$\sigma =$ volatility,
$\phi =$ random draw from a standard normal distribution

$^3$If this were not true, then I (and many others) would be rich

$^4$G. Box, of Box-Jenkins and Box-Muller fame.
Monte Carlo Paths: GBM

Figure: Ten realizations of possible random paths. Assumption: price processes are stochastic, i.e. unpredictable. $\mu = .10, \sigma = .25$. 
What’s Wrong with GBM?

- Equity return data suggests market has \textit{jumps} in addition to GBM
  - Sudden discontinuous changes in price
- Most asset allocation strategies ignore the jumps, i.e. market crashes
- But, it seems that we get a financial crisis occurring about once every ten years
- Does it make sense to ignore these events?
  - Jumps are also known as: \textbf{Black Swans} (see the book with the same title by Nassim Taleb)
  - Fat tail events
TSX Composite monthly log returns 1979-2014

Figure: Higher peaks, heavier tails than normal distribution
A Better Model: Jump Diffusion

\[
\frac{dS}{S} = \underbrace{(\mu - \lambda \kappa)}_{\text{GBM}} dt + \sigma \phi \sqrt{dt} + \underbrace{(J - 1) dq}_{\text{Jumps}}
\]

\[
dq = \begin{cases} 
0 & \text{with probability } 1 - \lambda dt \\
1 & \text{with probability } \lambda dt,
\end{cases}
\]

\[\lambda = \text{mean arrival rate of Poisson jumps}; \ S \rightarrow JS\]

\[J = \text{Random jump size}; \ \kappa = E[J - 1].\]

- GBM plus jumps (jump diffusion)
- When a jump occurs, \( S \rightarrow JS \), where \( J \) is also random
- This simulates a sudden market crash
Figure: The arrival rate of the Poisson jump process is .1 per year. Most of the time, the asset follows GBM. In only one of ten stochastic paths, in any given year, can we expect a crash. $\mu = .10, \sigma = .25$. 

Monte Carlo Paths
Example: Target Date (Lifecyle) Fund with two assets

Risk free bond $B$

\[ dB = rB \, dt \]
\[ r = \text{risk-free rate} \]

Amount in risky stock index $S$

\[ dS = \text{jump diffusion process} \]

Total wealth $W$

\[ W = S + B \quad (1) \]

Objective:
- Optimal allocation of amounts $(S(t), B(t))$, which is multi-period mean-variance optimal
- Optimal strategy is in general a function of $(W, t)$
Optimal Control

Let:

\[ X = (S(t), B(t)) = \text{Process} \]
\[ x = (S(t) = s, B(t) = b) = (s, b) = \text{State} \]
\[ (s + b) = \text{total wealth} \]

Let \((s, b) = (S(t^-), B(t^-))\) be the state of the portfolio the instant before applying a control.

The control \(c(s, b) = (d, B^+)\) generates a new state:

\[
\begin{align*}
  b & \rightarrow B^+ \\
  s & \rightarrow S^+ \\
  S^+ & = (s + b - B^+ - d)
\end{align*}
\]

Note: we allow cash withdrawals of an amount \(d \geq 0\) at a rebalancing time.
Semi-self financing policy

Since we allow cash withdrawals

→ The portfolio may not be self-financing
→ The portfolio may generate a free cash flow

Let \( W_a = S(t) + B(t) \) be the \textbf{allocated wealth}

\( W_a \) is the wealth available for allocation into \((S(t), B(t))\).

The non-allocated wealth \( W_n(t) \) consists of cash withdrawals and accumulated interest
Constraints on the strategy

The investor can continue trading only if solvent

\[ W_a(s, b) = s + b > 0. \]

Solvency condition

In the event of bankruptcy, the investor must liquidate

\[ S^+ = 0 \quad ; \quad B^+ = W_a(s, b) \quad ; \quad \text{if } W_a(s, b) \leq 0. \]

bankruptcy

Leverage is also constrained

\[ \frac{S^+}{W^+} \leq q_{\text{max}} \]

\[ W^+ = S^+ + B^+ = \text{Total Wealth} \]
Mean and Variance under control $c(X(t), t)$

Let:

\[
\begin{align*}
E_{t,x}^c(\cdot) [W_a(T)] & \quad \text{Reward} \\
\text{Var}_{t,x}^c(\cdot) [W_a(T)] & \quad \text{Risk}
\end{align*}
\]

\[
E_{t,x}^c(\cdot) [W_a(T)] = \text{Expectation conditional on } (x, t) \text{ under control } c(\cdot)
\]

\[
\text{Var}_{t,x}^c(\cdot) [W_a(T)] = \text{Variance conditional on } (x, t) \text{ under control } c(\cdot)
\]

Important:
- mean and variance of $W_a(T)$ are as observed at time $t$, initial state $x$. 
Basic problem: find Efficient frontier

We construct the efficient frontier by finding the optimal control $c(\cdot)$ which solves (for fixed $\lambda$) \(^5\)

$$\max_c \left\{ \underbrace{E_{t,x}^{c(\cdot)}[W_a(T)]}_{\text{Reward}} - \lambda \underbrace{\text{Var}_{t,x}^{c(\cdot)}[W_a(T)]}_{\text{Risk}} \right\}$$

1. Varying $\lambda \in [0, \infty)$ traces out the efficient frontier
2. $\lambda = 0; \rightarrow$ we seek only maximize cash received, we don’t care about risk.
3. $\lambda = \infty \rightarrow$ we seek only to minimize risk, we don’t care about the expected reward.

\(^5\)All investors should pick one of the strategies on the efficient frontier.
Each point on the efficient frontier represents a different strategy $c(\cdot)$. 

Conversely: given this expected value, no other point has a smaller variance.

Given this variance: no other point has a higher expected value.
Mean Variance: Standard Formulation

\[
\max_{c(X(u), u \geq t)} \left\{ \frac{E^{c(\cdot)}_{t, X} [W_a(T)]}{\text{Reward as seen at } t} - \lambda \frac{\text{Var}^{c(\cdot)}_{t, X} [W_a(T)]}{\text{Risk as seen at } t} \right\},
\]

\[\lambda \in [0, \infty)\] (4)

- Let \( c^*_t(x, u), u \geq t \) be the optimal policy for (4).

Then \( c^*_{t+\Delta t}(x, u), u \geq t + \Delta t \) is the optimal policy which maximizes

\[
\max_{c(X(u), u \geq t+\Delta t)} \left\{ \frac{E^{c(\cdot)}_{t+\Delta t, X(t+\Delta t)} [W_a(T)]}{\text{Reward as seen at } t+\Delta t} - \lambda \frac{\text{Var}^{c(\cdot)}_{t+\Delta t, X(t+\Delta t)} [W_a(T)]}{\text{Risk as seen at } t+\Delta t} \right\}.
\]
Pre-commitment Policy

However, in general

$$c_t^*(X(u), u) \neq c_{t+\Delta t}^*(X(u), u)$$

optimal policy as seen at $t$

optimal policy as seen at $t+\Delta t$

for any time $u \geq t + \Delta t$.

Optimal policy is not \textit{time-consistent}.

The strategy which solves problem (4) has been called the \textit{pre-commitment} policy

Your future self may not agree with your current self!
Ulysses and the Sirens: A pre-commitment strategy

Ulysses had himself tied to the mast of his ship (and put wax in his sailor’s ears) so that he could hear the sirens song, but not jump to his death.
Re-formulate MV Problem $\rightarrow$ Dynamic Programming\(^6\)

For fixed $\lambda$, if $c^*(\cdot)$ maximizes

$$
\max_{c(X(u), u \geq t)} \left\{ \underbrace{E_{t,x}^c[W_a(T)]}_{\text{Reward}} - \lambda \underbrace{\text{Var}_{t,x}^c[W_a(T)]}_{\text{Risk}} \right\},
$$

\rightarrow \text{There exists } \gamma \text{ such that } c^*(\cdot) \text{ minimizes}

$$
\min_{c(\cdot)} E_{t,x}^{c(\cdot)} \left[ \left(W_a(T) - \frac{\gamma}{2}\right)^2 \right].
$$

Once $c^*(\cdot)$ is known

- Easy to determine $E_{t,x}^{c^*(\cdot)}[W_a(T)]$, $\text{Var}_{t,x}^{c^*(\cdot)}[W_a(T)]$
- Repeat for different $\gamma$, traces out efficient frontier

\(^6\)Li and Ng (2000), Zhou and Li (2000)
Equivalence of MV optimization and target problem

MV optimization is equivalent\(^7\) to investing strategy which

- Attempts to hit a target final wealth of \(\gamma/2\)
- There is a quadratic penalty for not hitting this wealth target
- From (Li and Ng(2000))

\[
\frac{\gamma}{2} \quad \text{wealth target} = \frac{1}{2\lambda} \quad \text{risk aversion} + \mathbb{E}_{t=0,x_0}^{c(\cdot)}[W_a(T)] \quad \text{expected wealth}
\]

Intuition: if you want to achieve \(E[W_a(T)]\), you must aim higher

\(^7\)Vigna, Quantitative Finance, 2014
HJB PIDE

Determination of the optimal control $c(\cdot) \Rightarrow$ find the value function

$$V(x, t) = \min_{c(\cdot)} \left\{ E_{x,t}^{c(\cdot)} \left[ (W_a(T) - \gamma/2)^2 \right] \right\},$$

Value function
- Given from numerical solution of a Hamilton-Jacobi-Bellman (HJB) partial integro-differential equation (PIDE)
- This also generates the optimal control $c(\cdot)$. 
Optimal semi-self-financing strategy

Let

\[ F(t) = \frac{\gamma}{2} e^{-r(T-t)} \]

= discounted target wealth

Theorem (Dang and Forsyth (2014))

If \( W_a(t) > F(t) \), \( t \in [0, T] \), an optimal MV strategy is

- Withdraw cash \( W_a(t) - F(t) \) from the portfolio
- Invest the remaining amount \( F(t) \) in the risk-free asset.

What should you do with the cash you withdraw (the free cash)?

- Anything you like (e.g. buy an expensive car).
- You are better off withdrawing the cash!
Intuition: Multi-period mean-variance

Optimal target strategy: try to hit $W_a(T) = \gamma/2 = F(T)$.

If $W_a(t) > F(t) = F(T)e^{-r(T-t)}$, then the target can be hit exactly by

- Withdrawing $W_a(t) - F(t)$ from the portfolio
- Investing $F(t)$ in the risk free account

This strategy dominates any other MV strategy

- We never exceed the target
- No “upside penalization”

→ And the investor receives a bonus in terms of a free cash flow

---

8 Idea that withdrawing cash may be mean variance optimal was also suggested in (Ehrbar, J. Econ. Theory (1990))

**Objective:** verify that removing cash when wealth exceeds target is optimal.
Efficient Frontier: sometimes it's optimal to spend money

Figure: $T = 20$ years, $W_a(0) = 100$. 
Example II

Two assets: risk-free bond, index

- Risky asset follows GBM (no jumps)

According to Benjamin Graham\textsuperscript{9}, most investors should

- Pick a fraction $p$ of wealth to invest in an index fund (e.g. $p = 1/2$).
- Invest $(1 - p)$ in bonds
- Rebalance to maintain this asset mix

How much better is the optimal asset allocation vs. simple rebalancing rules?

<td>816.62</td>
<td>142.85</td>
<td>$\text{Prob}(W(T) &lt; 800) = 0.19$</td>
</tr>
</tbody>
</table>

Table: $T = 30$ years. $W(0) = 100$. Semi-self-financing: no trading if insolvent; maximum leverage = 1.5, rebalancing once/year.

Standard deviation reduced by 250%, shortfall probability reduced by $3 \times$
Cumulative Distribution Functions

$E[W_T] = 816.62$ for both strategies

Optimal policy: Contrarian:
- when market goes down $\rightarrow$ increase stock allocation;
- when market goes up $\rightarrow$ decrease stock allocation

Optimal allocation gives up gains $\gg$ target in order to reduce variance and probability of shortfall.

Investor must pre-commit to target wealth
Mean and standard deviation of the control

\[ p = \text{fraction in risky asset} \]

Mean of \( p \)
Standard Deviation of \( p \)

Time (years)

\[ 0 \quad 5 \quad 10 \quad 15 \quad 20 \quad 25 \quad 30 \]

\[ 0.1 \quad 0.2 \quad 0.3 \quad 0.4 \quad 0.5 \quad 0.6 \quad 0.7 \quad 0.8 \quad 0.9 \quad 1 \quad 1.1 \]
Typical Strategy for Target Date Fund: Linear Glide Path

Let $p$ be fraction in risky asset

$$p(t) = p_{\text{start}} + \frac{t}{T}(p_{\text{end}} - p_{\text{start}})$$

Choose parameters so that we get the same expected value as the optimal strategy

$$p_{\text{start}} = 1.0 \quad ; \quad p_{\text{end}} = 0.0$$

Conclusions

- Optimal allocation strategy dominates simple constant proportion strategy by a large margin
  - Probability of shortfall $\simeq$ 3 times smaller!

- But
  - Investors must pre-commit to a wealth target
  - Investors must commit to a long term strategy (> 20 years)
  - Investors buy-in when market crashes, de-risk when near target

- Standard “glide path” strategies of Target Date funds
  - Inferior to constant mix strategy\(^{12}\)
  - Constant mix strategy inferior to optimal control strategy

- Optimal stochastic control: teaches us an important life lesson
  - Decide on a life target ahead of time and stick with it
  - If you achieve your target, do not be greedy and want more

\(^{12}\)See also “The false promise of Target Date funds”, Esch and Michaud (2014); “Life-cycle funds: much ado about nothing?”, Graf (2013)
