WATERLOO

Outline

- Statistical learning
  - Bayesian learning
  - Maximum a posteriori
  - Maximum likelihood

- Learning from complete Data

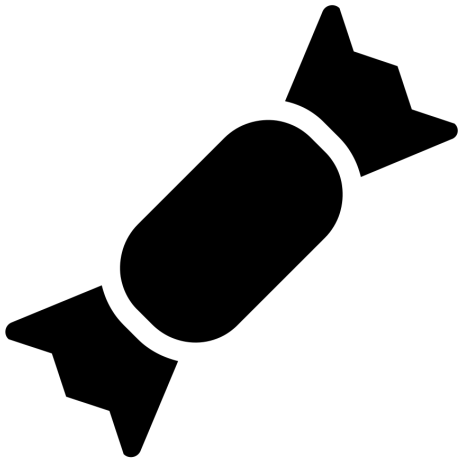
Statistical Learning

- View: we have uncertain knowledge of the world

- Idea: learning simply reduces this uncertainty

Candy Example

- Favorite candy sold in two flavors:
  - Lime (hugh)
  - Cherry (yum)
- Same wrapper for both flavors
- Sold in bags with different ratios:
  - 100% cherry
  - 75% cherry + 25% lime
  - 50% cherry + 50% lime
  - 25% cherry + 75% lime
  - 100% lime



Candy Example

- You bought a bag of candy but don't know its flavor ratio

- After eating k candies:
  - What's the flavor ratio of the bag?
  - What will be the flavor of the next candy?

Statistical Learning

- Hypothesis H: probabilistic theory of the world
  - h_1: 100% cherry
  - h_2: 75% cherry + 25% lime
  - h_3: 50% cherry + 50% lime
  - h_4: 25% cherry + 75% lime
  - h_5: 100% lime
- Data D: evidence about the world
  - d_1: 1st candy is cherry
  - d_2: 2nd candy is lime
  - d_3: 3rd candy is lime
  - …

Bayesian Learning

- Prior: Pr(H)
- Likelihood: Pr(d|H)
- Evidence: **d** = <d_1,d_2,…,d_n>

- Bayesian Learning amounts to computing the posterior using Bayes' Theorem:

$$Pr(H|\mathbf{d}) = k\ Pr(\mathbf{d}|H)Pr(H)$$

Bayesian Prediction

- Suppose we want to make a prediction about an unknown quantity X (i.e., the flavor of the next candy)

- $\Pr(X|\mathbf{d}) = \Sigma_i \Pr(X|\mathbf{d},h_i)P(h_i|\mathbf{d})$
  $= \Sigma_i \Pr(X|h_i)P(h_i|\mathbf{d})$

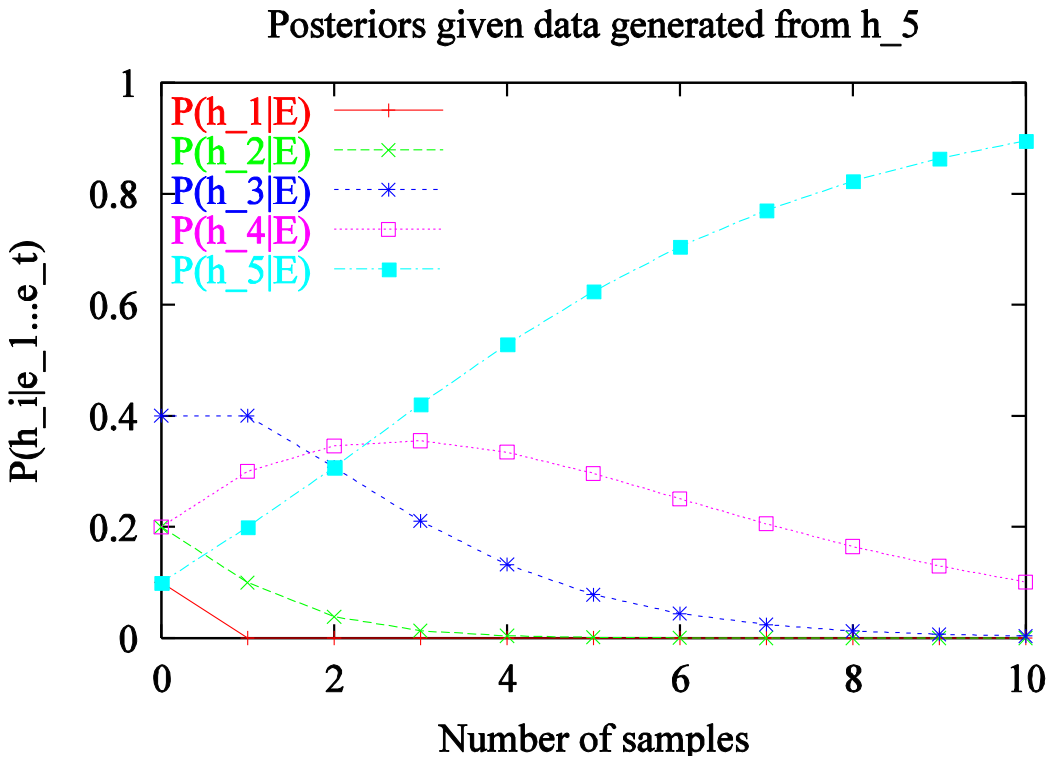
- Predictions are weighted averages of the predictions of the individual hypotheses
- Hypotheses serve as "intermediaries" between raw data and prediction

Candy Example

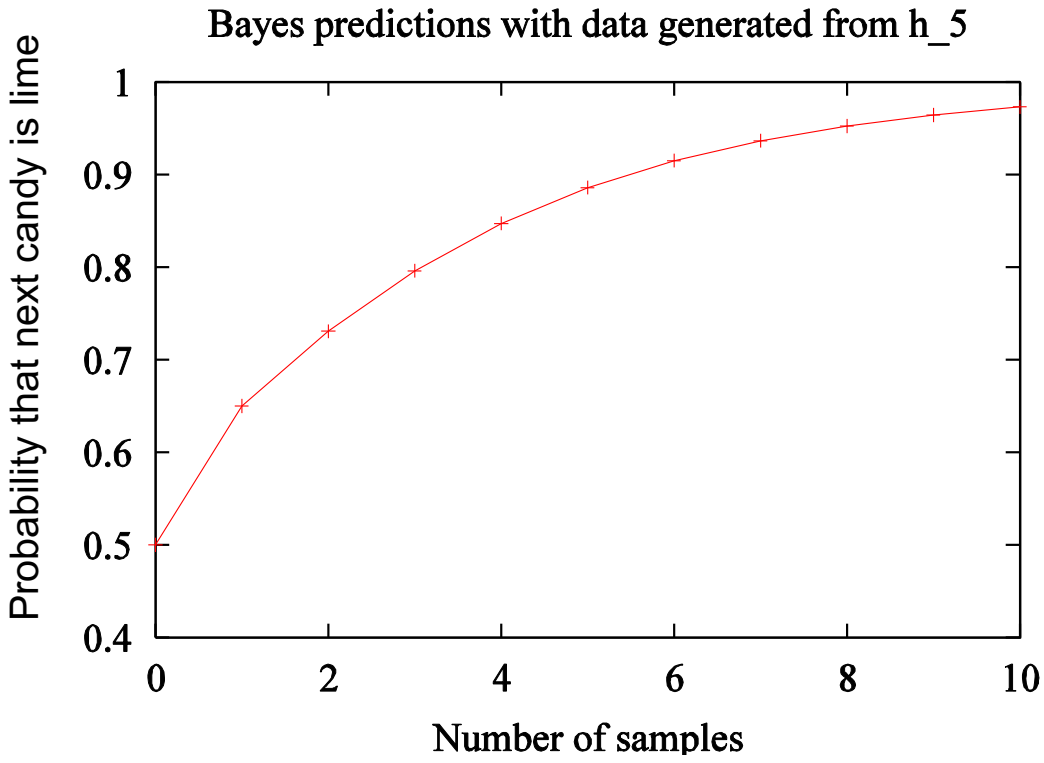
- Assume prior P(H) = <0.1, 0.2, 0.4, 0.2, 0.1>
- Assume candies are i.i.d. (identically and independently distributed)
  - $P(\mathbf{d}|h) = \Pi_j P(d_j|h)$

- Suppose first 10 candies all taste lime:
  - $P(\mathbf{d}|h_5) =$ $1^{10} = 1$
  - $P(\mathbf{d}|h_3) =$ $0.5^{10} \approx 0.001$
  - $P(\mathbf{d}|h_1) =$ $0^{10} = 0$

Posterior



Prediction



Bayesian Learning

- Bayesian learning properties:
  - **Optimal** (i.e., given prior, no other prediction is correct more often than the Bayesian one)
  - **No overfitting** (all hypotheses weighted and considered)

- There is a price to pay:
  - When hypothesis space is large Bayesian learning may be intractable
  - i.e., sum (or integral) over hypotheses often intractable
- Solution: approximate Bayesian learning

Maximum a posteriori (MAP)

- Idea: make prediction based on most probable hypothesis h_{MAP}
  - $h_{MAP} = \text{argmax}_{h_i} P(h_i|\mathbf{d})$
  - $P(X|\mathbf{d}) \approx P(X|h_{MAP})$

- In contrast, Bayesian learning makes prediction based on **all** hypotheses weighted by their probability

Candy Example (MAP)

- Prediction after
  - 1 lime: $h_{MAP} = h_3$, $Pr(lime|h_{MAP}) = 0.5$
  - 2 limes: $h_{MAP} = h_4$, $Pr(lime|h_{MAP}) = 0.75$
  - 3 limes: $h_{MAP} = h_5$, $Pr(lime|h_{MAP}) = 1$
  - 4 limes: $h_{MAP} = h_5$, $Pr(lime|h_{MAP}) = 1$
  - …

- After only 3 limes, it correctly selects h_5

Candy Example (MAP)

- But what if correct hypothesis is h_4?
  - h_4: P(lime) = 0.75 and P(cherry) = 0.25

- After 3 limes
  - MAP incorrectly predicts h_5
  - MAP yields $P(\text{lime}|h_{MAP}) = 1$
  - Bayesian learning yields $P(\text{lime}|\mathbf{d}) = 0.8$

MAP properties

- MAP prediction **less accurate** than Bayesian prediction since it relies only on **one** hypothesis h_{MAP}
- But MAP and Bayesian predictions converge as data increases
- Controlled overfitting (prior can be used to penalize complex hypotheses)

- Finding h_{MAP} may be intractable:
  - $h_{MAP} = \text{argmax } P(h|\mathbf{d})$
  - Optimization may be difficult

MAP computation

- Optimization:
  - $h_{MAP} = \text{argmax}_h \, P(h|\mathbf{d})$
    $= \text{argmax}_h \, P(h) \, P(\mathbf{d}|h)$
    $= \text{argmax}_h \, P(h) \, \Pi_i \, P(d_i|h)$

- Product induces non-linear optimization
- Take the log to linearize optimization
  - $h_{MAP} = \text{argmax}_h \log P(h) + \Sigma_i \log P(d_i|h)$

Maximum Likelihood (ML)

- Idea: simplify MAP by assuming uniform prior (i.e., $P(h_i) = P(h_j)\ \forall i,j$)
  - $h_{MAP} = \text{argmax}_h\ P(h)\ P(\mathbf{d}|h)$
  - $h_{ML} = \text{argmax}_h\ P(\mathbf{d}|h)$

- Make prediction based on h_{ML} only:
  - $P(X|\mathbf{d}) \approx P(X|h_{ML})$

Candy Example (ML)

- Prediction after
  - 1 lime: $h_{ML} = h_5$, $Pr(\text{lime}|h_{ML}) = 1$
  - 2 limes: $h_{ML} = h_5$, $Pr(\text{lime}|h_{ML}) = 1$
  - …

- Frequentist: "objective" prediction since it relies only on the data (i.e., no prior)
- Bayesian: prediction based on data and uniform prior (since no prior ≡ uniform prior)

ML properties

- ML prediction **less accurate** than Bayesian and MAP predictions since it ignores prior info and relies only on **one** hypothesis h_{ML}
- But ML, MAP and Bayesian predictions converge as data increases
- Subject to overfitting (no prior to penalize complex hypothesis that could exploit statistically insignificant data patterns)

- Finding h_{ML} is often easier than h_{MAP}
  - $h_{ML} = \text{argmax}_h \Sigma_i \log P(d_i|h)$

Statistical Learning

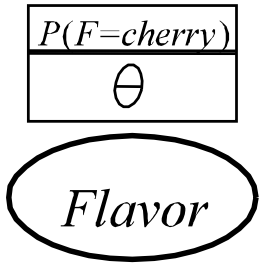
- Use Bayesian Learning, MAP or ML

- Complete data:
  - When data has multiple attributes, **all attributes are known**
  - Easy

- Incomplete data:
  - When data has multiple attributes, **some attributes are unknown**
  - Harder

Simple ML example

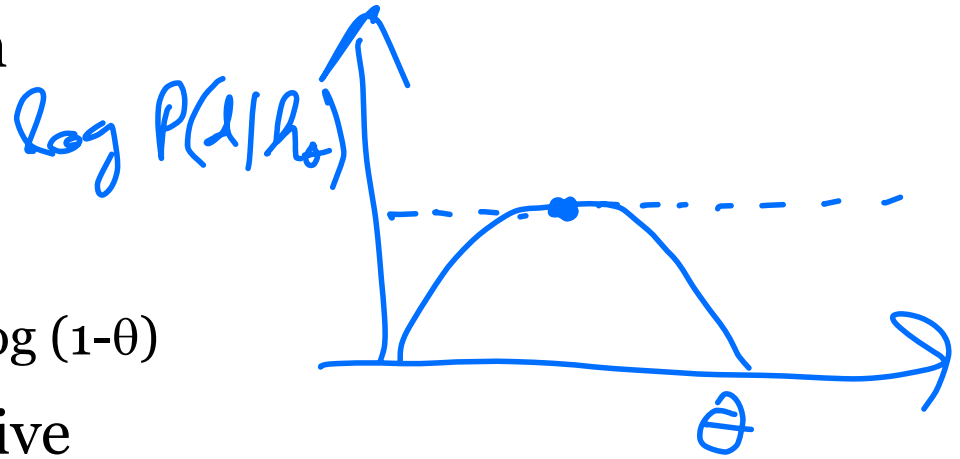
- Hypothesis h_θ:
  - P(cherry)=θ & P(lime)=1-θ
- Data **d**:
  - c cherries and l limes



- ML hypothesis:
  - θ is relative frequency of observed data
  - θ = c/(c+l)
  - P(cherry) = c/(c+l) and P(lime)= l/(c+l)

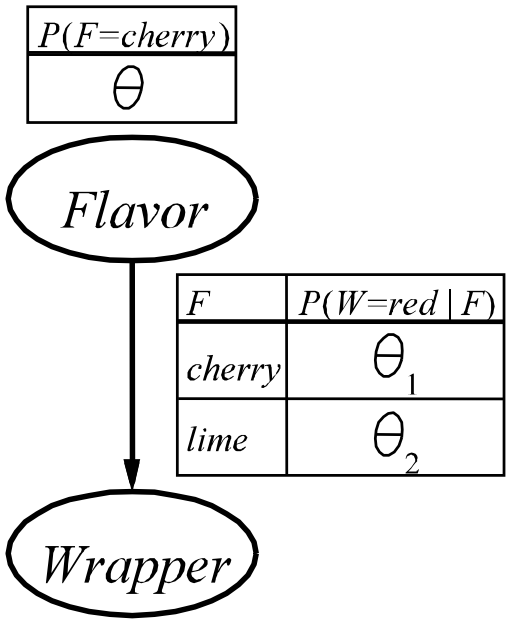
ML computation

- 1) Likelihood expression
  - $P(\mathbf{d}|h_\theta) = \theta^c (1-\theta)^l$
- 2) log likelihood
  - $\log P(\mathbf{d}|h_\theta) = c \log \theta + l \log (1-\theta)$
- 3) log likelihood derivative
  - $d(\log P(\mathbf{d}|h_\theta))/d\theta = c/\theta - l/(1-\theta)$
- 4) ML hypothesis
  - $c/\theta - l/(1-\theta) = 0 \rightarrow \theta = c/(c+l)$



More complicated ML example

- Hypothesis: $h_{\theta,\theta_1,\theta_2}$
- Data:
  - c cherries
    - g_c green wrappers
    - r_c red wrappers
  - l limes
    - g_l green wrappers
    - r_l red wrappers



ML computation

- 1) Likelihood expression
  - $P(\mathbf{d}|h_{\theta,\theta_1,\theta_2}) = \theta^c(1-\theta)^l\,\theta_1^{r_c}(1-\theta_1)^{g_c}\,\theta_2^{r_l}(1-\theta_2)^{g_l}$
- …
- 4) ML hypothesis
  - $c/\theta - l/(1-\theta) = 0 \rightarrow \theta = c/(c+l)$
  - $r_c/\theta_1 - g_c/(1-\theta_1) = 0 \rightarrow \theta_1 = r_c/(r_c+g_c)$
  - $r_l/\theta_2 - g_l/(1-\theta_2) = 0 \rightarrow \theta_2 = r_l/(r_l+g_l)$

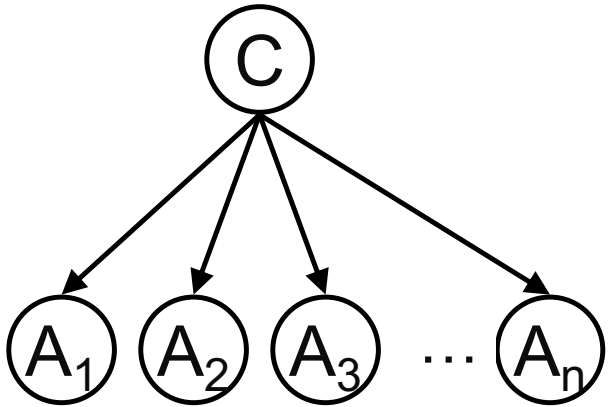
Laplace Smoothing

- An important case of overfitting happens when there is no sample for a certain outcome
  - E.g., no cherries eaten so far
  - P(cherry) = θ = c/(c+l) = 0
  - Zero probabilities are dangerous: they rule out outcomes

- Solution: Laplace (add-one) smoothing
  - Add 1 to all counts
  - P(cherry) = θ = (c+1)/(c+l+2) > 0
  - Much better results in practice

Naïve Bayes model

- Want to predict a class C based on attributes A_i
- Parameters:
  - θ = P(C=true)
  - θ_{i1} = P(A_i=true|C=true)
  - θ_{i2} = P(A_i=true|C=false)



- Assumption: A_i's are independent given C

Naïve Bayes model for Restaurant Problem

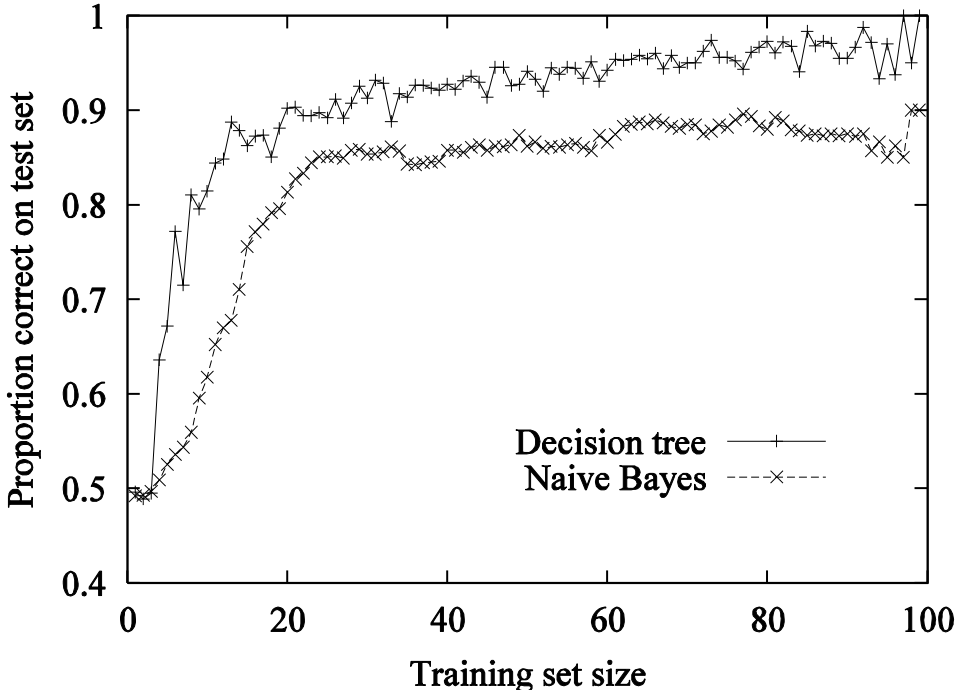
- Data:

Example	Attributes										Target
	Alt	*Bar*	*Fri*	*Hun*	*Pat*	*Price*	*Rain*	*Res*	*Type*	*Est*	*Wait*
X_1	T	F	F	T	Some	$$$	F	T	French	0–10	T
X_2	T	F	F	T	Full	$	F	F	Thai	30–60	F
X_3	F	T	F	F	Some	$	F	F	Burger	0–10	T
X_4	T	F	T	T	Full	$	F	F	Thai	10–30	T
X_5	T	F	T	F	Full	$$$	F	T	French	>60	F
X_6	F	T	F	T	Some	$$	T	T	Italian	0–10	T
X_7	F	T	F	F	None	$	T	F	Burger	0–10	F
X_8	F	F	F	T	Some	$$	T	T	Thai	0–10	T
X_9	F	T	T	F	Full	$	T	F	Burger	>60	F
X_{10}	T	T	T	T	Full	$$$	F	T	Italian	10–30	F
X_{11}	F	F	F	F	None	$	F	F	Thai	0–10	F
X_{12}	T	T	T	T	Full	$	F	F	Burger	30–60	T

- Maximum likelihood:
  - θ = relative frequencies of *wait* and *~wait*
  - θ_{i1}, θ_{i2} = relative frequencies of each attribute value given *wait* and *~wait*

Naïve Bayes Model vs Decision Trees

- Wait prediction for restaurant problem



Why is naïve Bayes less accurate than decision tree?

Bayesian Network Parameter Learning (Max Likelihood)

- Parameters $\theta_{V,pa(V)=\mathbf{v}}$:
  - CPTs: $\theta_{V,pa(V)=\mathbf{v}} = P(V|pa(V)=\mathbf{v})$
- Data $\mathbf{d}$:
  - $d_1 : <V_1=v_{1,1}, V_2=v_{2,1}, ..., V_n = v_{n,1}>$
  - $d_2 : <V_1=v_{1,2}, V_2=v_{2,2}, ..., V_n = v_{n,2}>$
  - ...
- Maximum likelihood:
  - Set $\theta_{V,pa(V)=\mathbf{v}}$ to the relative frequencies of the values of V given the values $\mathbf{v}$ of the parents of V

$$\theta_{V,pa(V)=\mathbf{v}} = \#(V,pa(V)=\mathbf{v}) / \#(pa(V)=\mathbf{v})$$
