

Query Optimization

CS348 Spring 2023

Instructor: Sujaya Maiyya

Sections: **002 & 004 only**

Overview

- Many different ways of processing the same query
 - Scan? Sort? Hash? Use an index?
 - All have different performance characteristics and/or make different assumptions about data
- Best choice depends on the situation
 - Implement all alternatives
 - Let the query optimizer choose at run-time (this lecture)

last lecture

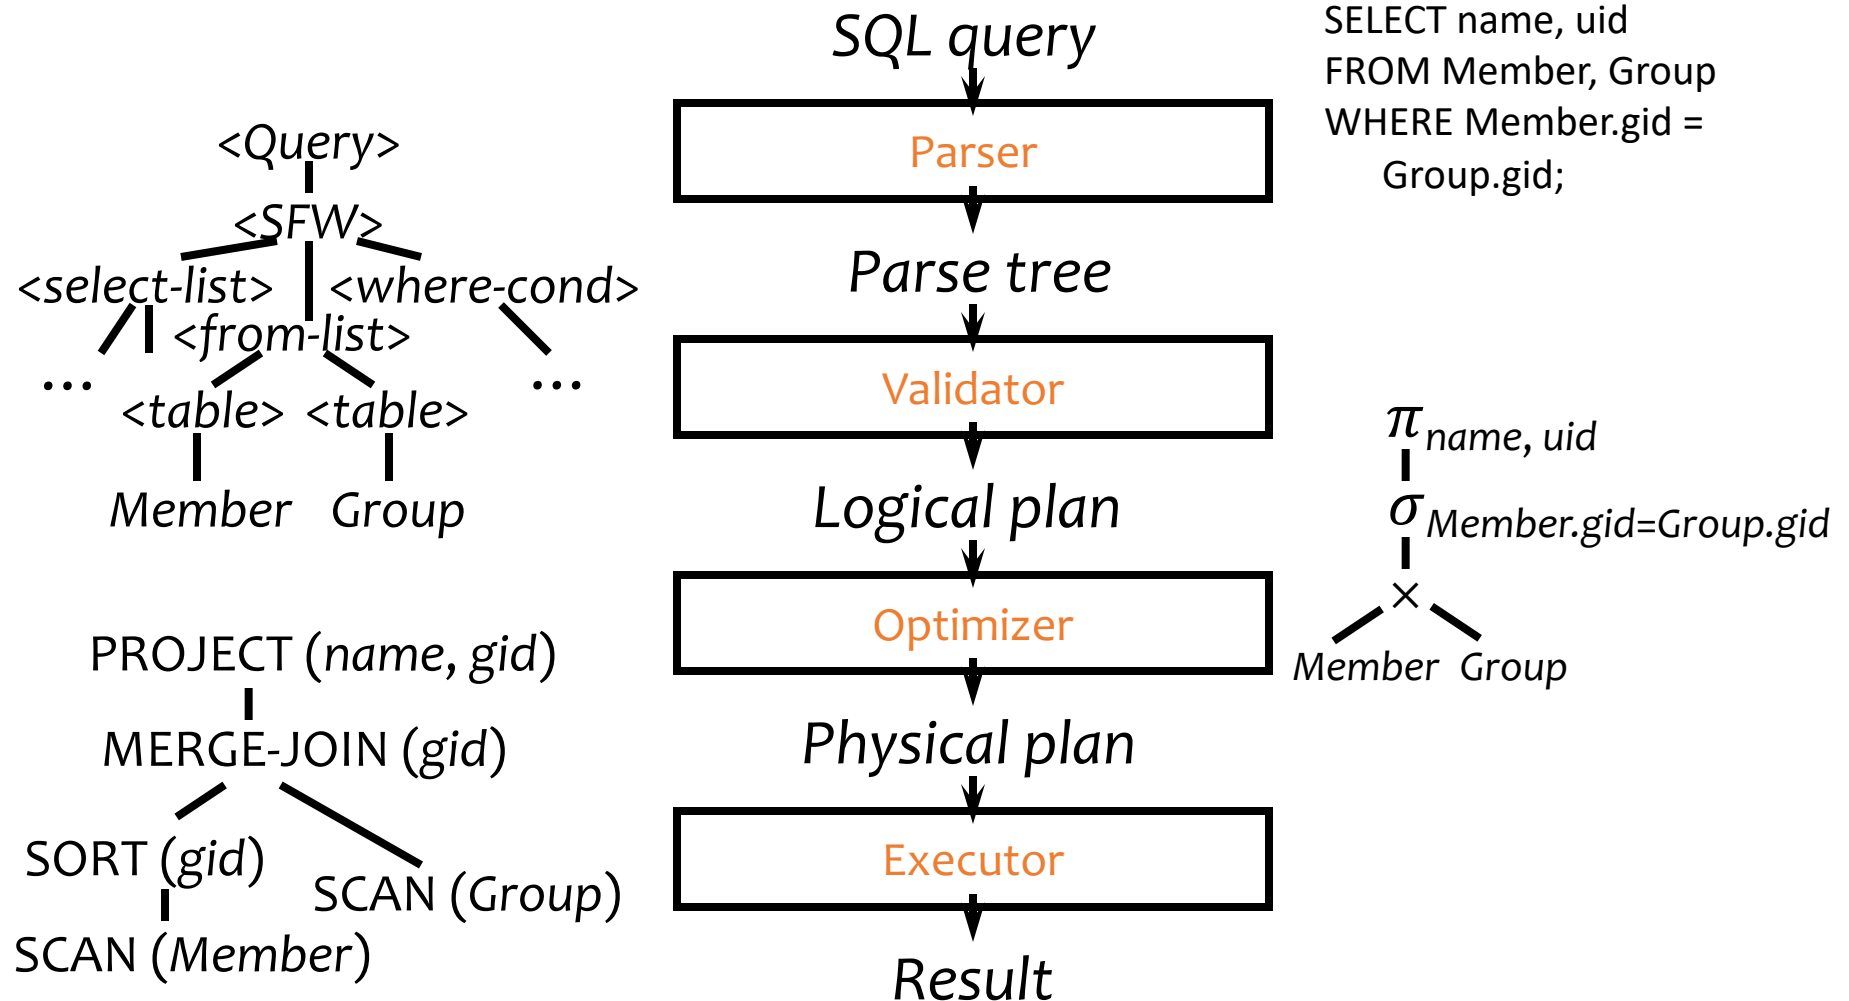

Overview (cont.)

Outline

- System view of query processing
 - Logical plan and physical plan
 - Cost calculation of the physical plan
 - Cardinality estimation
 - Search space and search strategy
 - Transformation rules
- } Cost based optimization
- } Heuristic or Rule based optimization

A query's trip through the DBMS

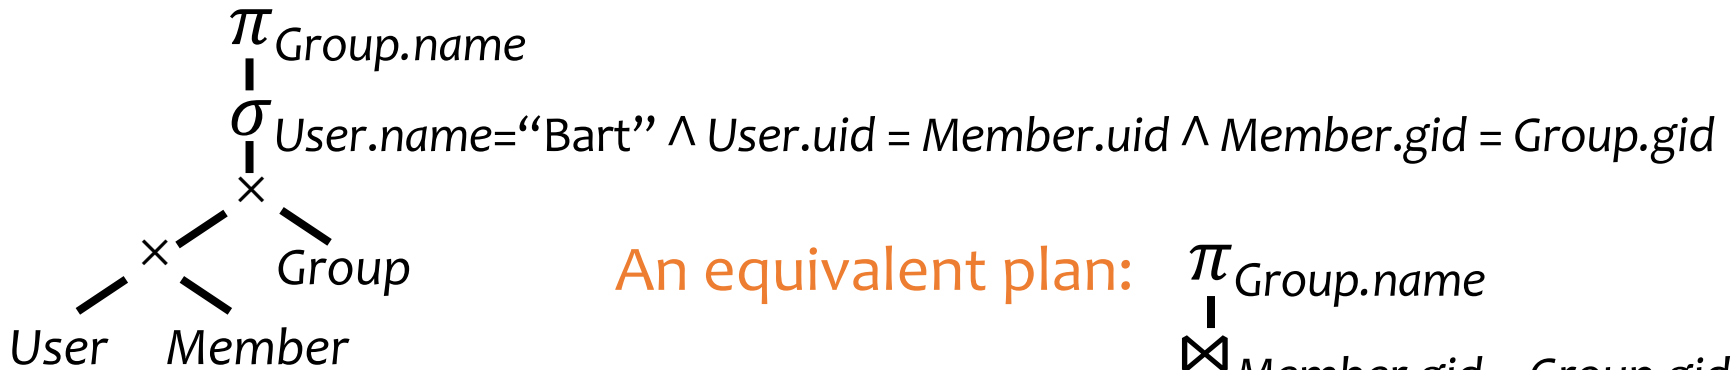

Parsing and validation

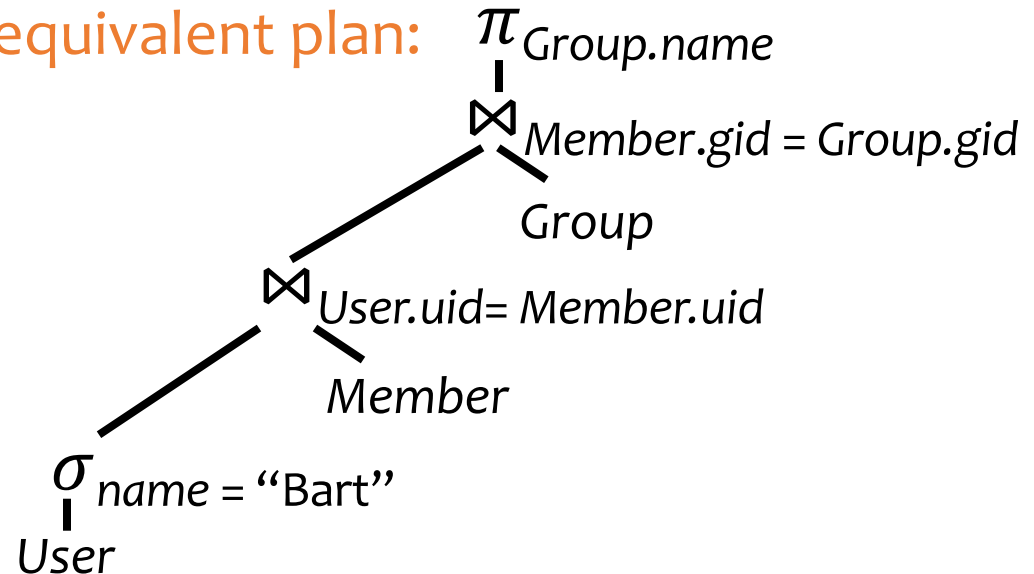

- **Parser: SQL → parse tree**
 - Detect and reject **syntax** errors
- **Validator: parse tree → logical plan**
 - Detect and reject **semantic** errors
 - Nonexistent tables/views/columns?
 - Insufficient access privileges?
 - Type mismatches?
 - Examples: AVG(name), name + pop, User UNION Member
 - Also
 - Expand *
 - Expand view definitions
 - Information required for semantic checking is found in **system catalog** (which contains all schema information)

Logical plan

- Nodes are **logical** operators (often relational algebra operators)
- There are many equivalent logical plans

An equivalent plan:

Physical (execution) plan

- A complex query may involve multiple tables and various query processing algorithms
 - E.g., table scan, basic & block nested-loop join, index nested-loop join, sort-merge join, ... (Lecture 13)
- A **physical plan** for a query tells the DBMS query processor how to execute the query
 - A tree of **physical plan operators**
 - Each operator implements a query processing algorithm
 - Each operator accepts a number of input tables/streams and produces a single output table/stream

Examples of physical plans

```
SELECT Group.name  
FROM User, Member, Group  
WHERE User.name = 'Bart'  
AND User.uid = Member.uid AND Member.gid = Group.gid;
```

- Many physical plans for a single query
 - Equivalent results, but different costs and assumptions!
 - 👉 **DBMS query optimizer picks the “best” possible physical plan**

Cost estimation

Physical plan example:

Input to Join(*uid*):

What is its input size?
How many tuples with
name='Bart'?

- We have: cost estimation for each operator
 - Example: INDEX-NESTED-LOOP-JOIN(*uid*) takes $O(B(R) + |R| \cdot (\text{index lookup} + \text{record fetch}))$
- We need: size of intermediate results

Lecture 13

Cardinality estimation

Cardinality estimation for:

- Equality predicates
- Range predicates
- Joins
- Textbook has more operators

Selections with equality predicates

- $Q: \sigma_{A=v}R$
- DBMSs typically store the following in the catalog
 - Size of R : $|R|$
 - Number of distinct A values in R : $|\pi_A R|$
- Assumptions
 - Values of A are uniformly distributed in R
- $|Q| \approx |R| / |\pi_A R|$
 - Selectivity factor of $(A = v)$ is $1 / |\pi_A R|$

Example

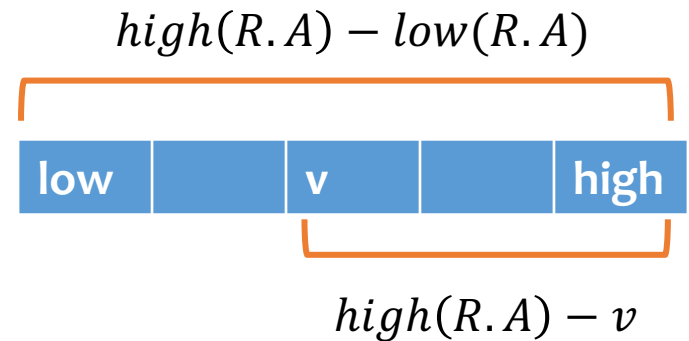

Physical plan example:

- $|User|=1000, |\pi_{name}(User)| = 50 \rightarrow |\sigma_{name="Bart"}(User)| = ?$
- Assumptions:
 - Values of *name* are uniformly distributed in *User*
- $|\sigma_{name="Bart"}(User)| = \frac{1000}{50} = 20$

Range predicates

- $Q: \sigma_{A>v}R$
- Not enough information!
 - Just pick, say, $|Q| \approx |R| \cdot 1/3$
- With more information
 - Largest R.A value: $high(R.A)$
 - Smallest R.A value: $low(R.A)$
 - $|Q| \approx |R| \cdot \frac{high(R.A)-v}{high(R.A)-low(R.A)}$

Two-way equi-join

- $Q: R(A, B) \bowtie S(A, C)$
- Assumption: **containment of value sets**
 - Every tuple in the “smaller” relation (one with fewer distinct values for the join attribute) joins with some tuple in the other relation
 - That is, if $|\pi_A R| \leq |\pi_A S|$ then $\pi_A R \subseteq \pi_A S$
 - Certainly not true in general
 - But holds in the common case of foreign key joins
- $|Q| \approx \frac{|R| \cdot |S|}{\max(|\pi_A R|, |\pi_A S|)}$
 - Selectivity factor of $R.A = S.A$ is $1 / \max(|\pi_A R|, |\pi_A S|)$

Example

- Database:
 - $User(\underline{uid}, name, age, pop)$, $Member(\underline{gid}, \underline{uid}, date)$, $Group(\underline{gid}, gname)$
 - $|User|=1000$ rows, $|Group|=100$ rows, $|Member|=50000$ rows
 - $|\pi_{name}(User)| = 50$
 - $|\pi_{uid}(Member)| = 500$
- Estimate size $|User \bowtie Member| = ?$
 - $|\pi_{uid}(User)| = 1000$
 - $|\pi_{uid}(Member)| = 500$
 - $1000 * 50000 / \max(500, 1000) = 50000$

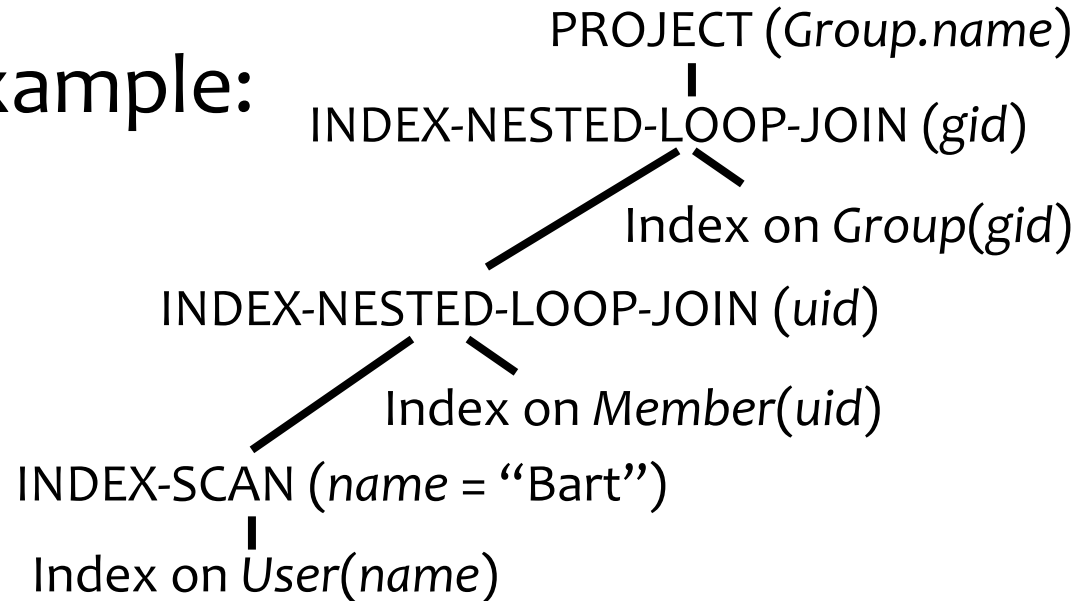

Other estimations

- Using similar ideas, we can estimate the size of projection, duplicate elimination, union, difference, aggregation (with grouping)
- Lots of assumptions and very rough estimation
 - Accurate estimate is not needed
 - Maybe okay if we overestimate or underestimate
- Not covered: better estimation using **histograms**
 - Instead of assuming uniform distribution, use the frequency from the histogram

Case Study

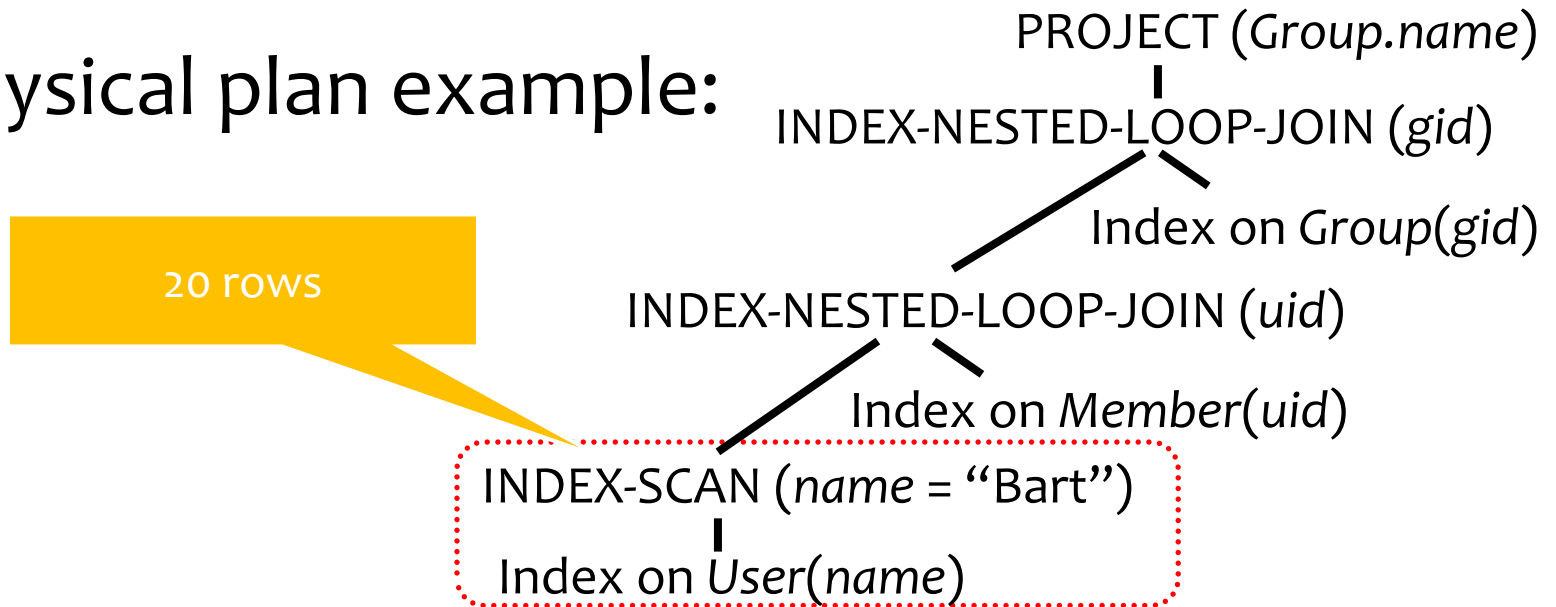

Physical plan example:

- System requirements:
 - Each disk/memory block can hold up to 10 rows (from any table);
 - All tables are stored compactly on disk (10 rows per block);
 - 8 memory blocks are available for query processing: $M=8$
- Database:
 - User(uid, age, pop), Member(gid,uid,date), Group(gid, gname)
 - |User|=1000 rows, |Group|=100 rows, |Member|=50000 rows
 - #of blocks: B(User)=1000/10=100; B(Group)=100/10=10; B(Member)=50000/10=5k

Case Study

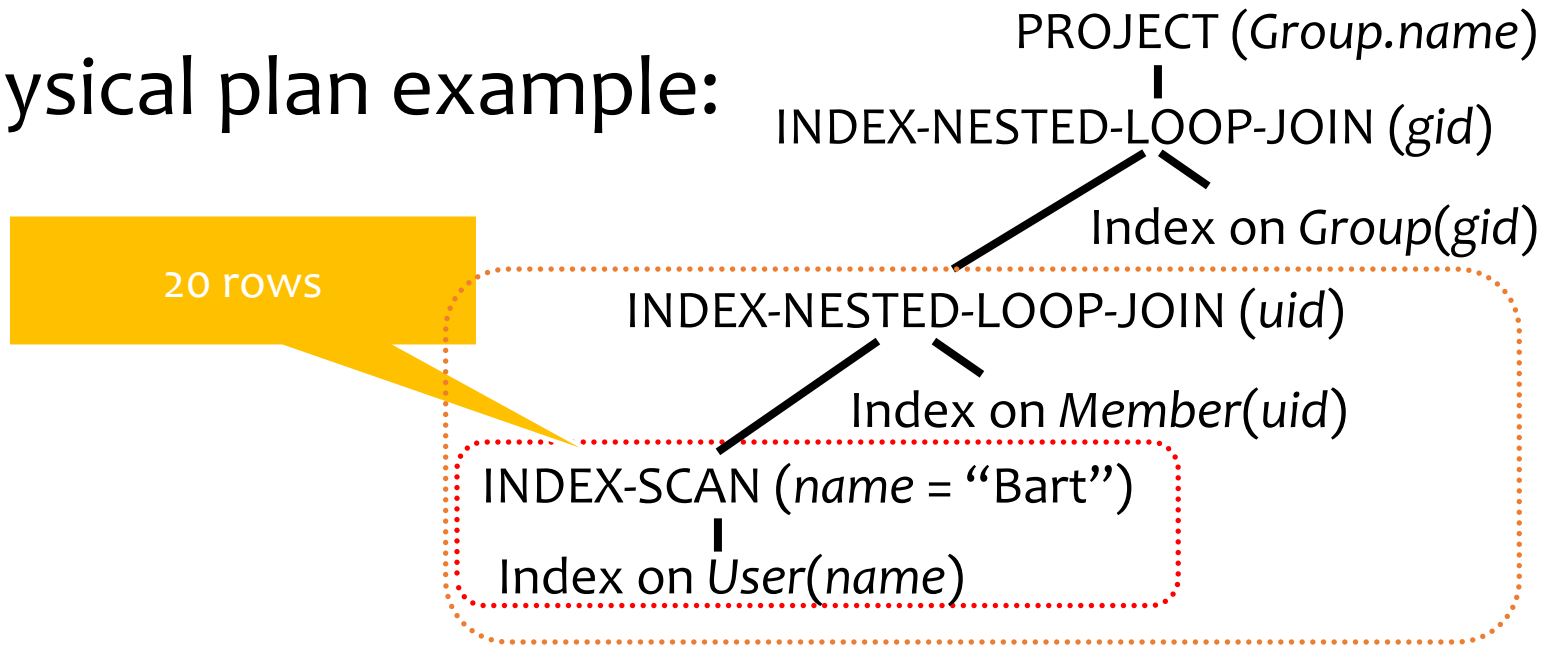

Physical plan example:

- Given $|User|=1000$, $|\pi_{name}(User)| = 50$
 - $\rightarrow |\sigma_{name="Bart"}(User)| = \frac{1000}{50} = 20$ records
- INDEX-SCAN on User
 - IO COST: index lookup (4 IOs, depending on the height of the index tree)

Case Study

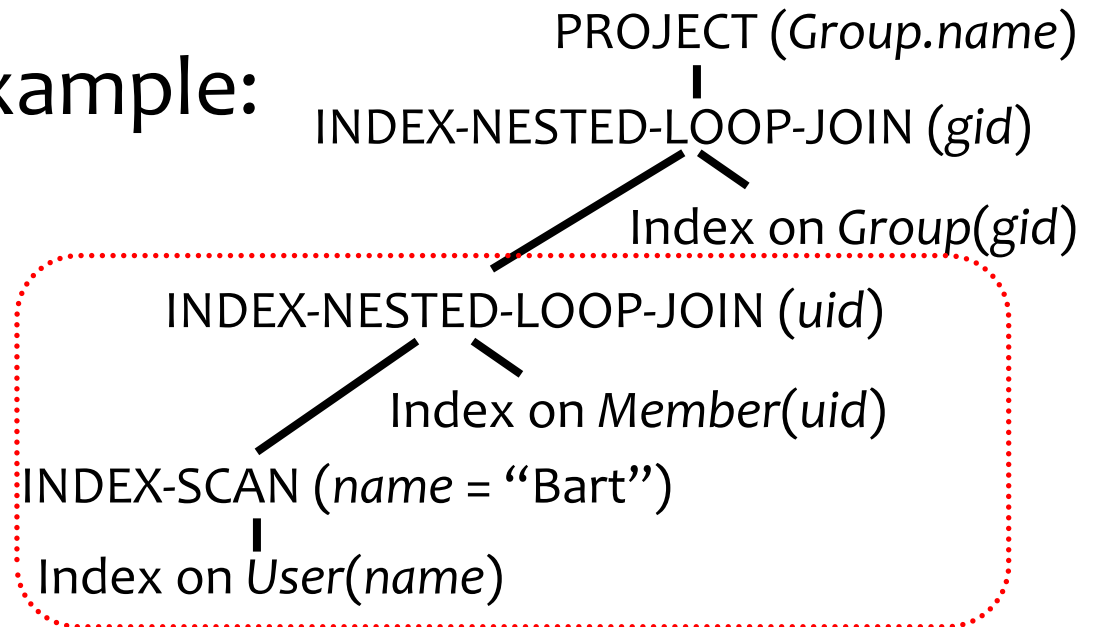

Physical plan example:

- $|User|=1000, |\pi_{name}(User)| = 50 \rightarrow |\sigma_{name="Bart"}(User)| = \frac{1000}{50} = 20$ records
- INDEX-SCAN on User
 - IO COST: index lookup (4 IOs, depending on the height of the index tree)
- JOIN: For each record with name = "Bart", probe the index on *Member(uid)*
 - IO cost: $B(R) + |R| \cdot (\text{index lookup} + \text{record fetch})$
 - 20 rows are not clustered \rightarrow at worst case, 20 blocks of data to be retrieved
 - $20 + 20 * (4 \text{ IOs for index} + \text{record fetches})$

Case Study

Physical plan example:

- Given $|\pi_{uid}(\sigma_{name="Bart"}User)| = 20$, $|\pi_{uid}(Member)| = 500$
- $|JOIN(uid)| \approx \frac{|R| \cdot |S|}{\max(|\pi_{AR}|, |\pi_{AS}|)} = \frac{20 \cdot 50k}{\max(20, 500)} = \frac{1000k}{500} = 2k$
- $|JOIN(gid)| = ?$

Case Study

Physical plan example:

Input = JOIN(uid)

- Given $| \text{Input} | = 2k$, say $| \pi_{gid}(\text{Input}) | = 50$, $| \text{Group} | = 100$, $| \pi_{gid}(\text{Group}) | = 100$,
- $| \text{JOIN}(gid) | \approx \frac{|R| \cdot |S|}{\max(|\pi_{AR}|, |\pi_{AS}|)} = \frac{2k \cdot 100}{\max(50, 100)} = \frac{200k}{100} = 2k$

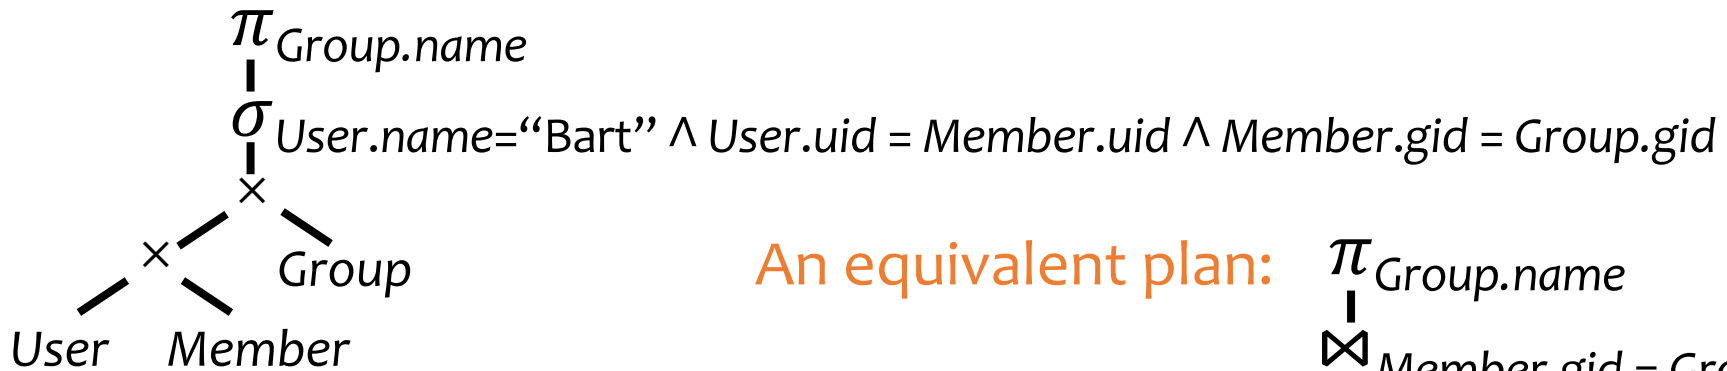

Outline

- System view of query processing
 - Logical plan and physical plan
- Cost calculation of the physical plan
 - Cardinality estimation
- Search space and search strategy
 - Transformation rules
 - Heuristic approach

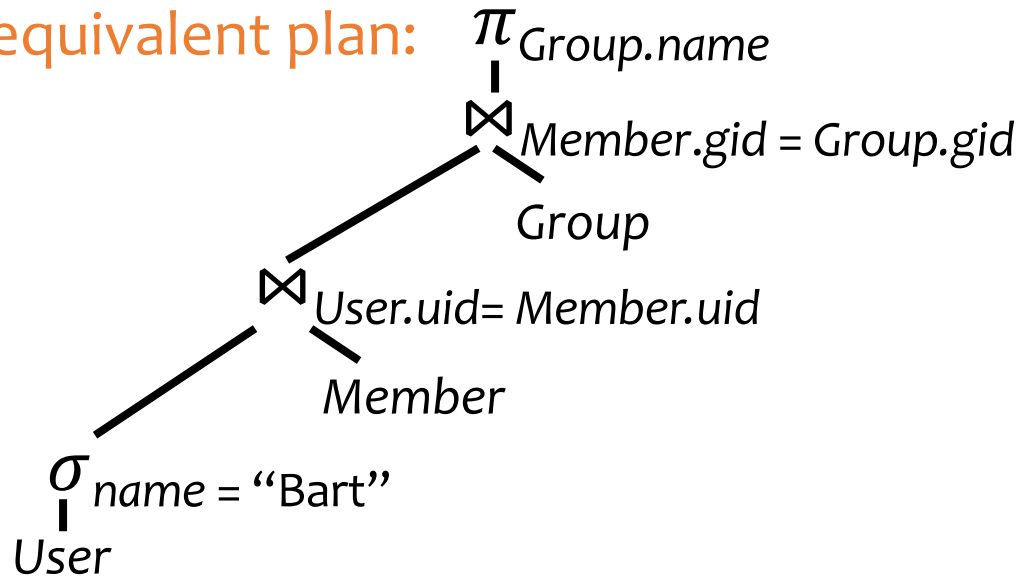

Search space is huge

- Characterized by “equivalent” logical query plans

SELECT Group.name FROM User, Member, Group WHERE User.name = 'Bart'
AND User.uid = Member.uid AND Member.gid = Group.gid;

An equivalent plan:

Do we need to exam all the logical plans?

No. We can apply heuristic transformation rules to find a cheaper logical plan

Transformation rules (a sample)

- Convert σ_p - \times to/from \bowtie_p : $\sigma_p(R \times S) = R \bowtie_p S$
 - Example: $\sigma_{User.uid=Member.uid}(User \times Member) = User \bowtie Member$
- Merge/split σ 's: $\sigma_{p_1}(\sigma_{p_2}R) = \sigma_{p_1 \wedge p_2}R$
 - Example: $\sigma_{age>20}(\sigma_{pop=0.8}User) = \sigma_{age>20 \wedge pop=0.8}User$
- Merge/split π 's: $\pi_{L_1}(\pi_{L_2}R) = \pi_{L_1}R$, if $L_1 \subseteq L_2$
 - Example: $\pi_{age}(\pi_{age,pop}User) = \pi_{age}User$

Transformation rules (a sample)

- Push down/pull up σ :

$$\sigma_{p \wedge p_r \wedge p_s}(R \bowtie_{p'} S) = (\sigma_{p_r} R) \bowtie_{p \wedge p'} (\sigma_{p_s} S), \text{ where}$$

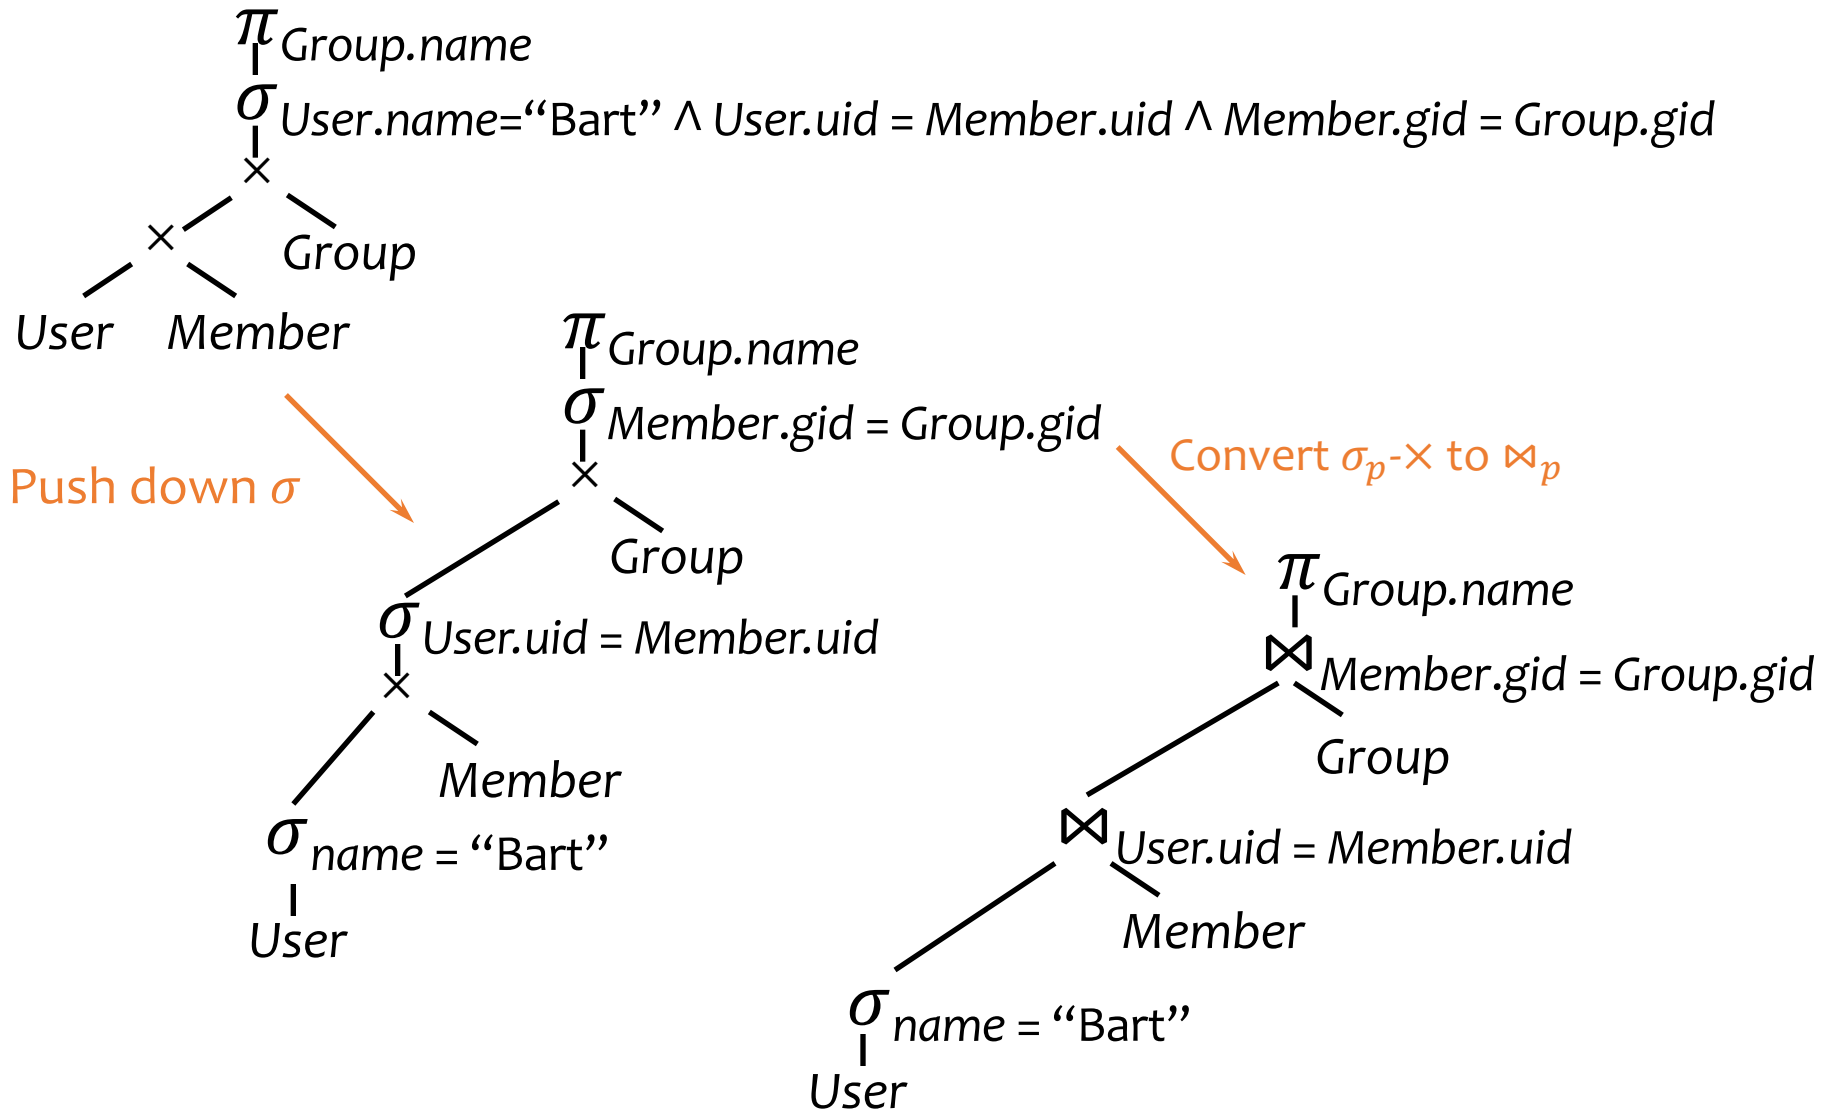

- p_r is a predicate involving only R columns
- p_s is a predicate involving only S columns
- p and p' are predicates involving both R and S columns
- Example:

$$\begin{aligned} & \sigma_{U1.name=U2.name \wedge U1.pop>0.8 \wedge U2.pop>0.8}(\rho_{U1} User \bowtie_{U1.uid \neq U2.uid} \rho_{U2} User) \\ &= \sigma_{pop>0.8}(\rho_{U1} User) \bowtie_{U1.uid \neq U2.uid \wedge U1.name=U2.name} (\sigma_{pop>0.8}(\rho_{U2} User)) \end{aligned}$$

Transformation rules (a sample)

- Push down π : $\pi_L(\sigma_p R) = \pi_L(\sigma_p(\pi_{L,L'} R))$, where
 - L' is the set of columns referenced by p that are not in L
 - Example:
$$\pi_{age}(\sigma_{pop>0.8} User) = \pi_{age}(\sigma_{pop>0.8}(\pi_{age,pop} User))$$
- Many more (seemingly trivial) equivalences...
 - Can be systematically used to transform a plan to new ones

Relational query rewrite example

Heuristics-based query optimization

- Start with a logical plan
- Push selections/projections down as much as possible
 - Why? Reduce the size of intermediate results
- Join smaller relations first, and avoid cross product
 - Why? Joins are more optimized and have alternate implementations
- Convert the transformed logical plan to a physical plan (by choosing appropriate physical operators)

Search strategy

- **Heuristics-based optimization**

- Apply heuristics to rewrite “logical plans” into cheaper ones

- **Cost-based optimization**

- Need statistics to estimate sizes of intermediate results to find the best “physical plan”

→ Course CS448 “Database Systems Implementation”

Summary

- System view of query processing
 - Logical plan and physical plan
- Cost calculation of the physical plan
 - Cardinality estimation
- Search space and search strategy
 - Transformation rules
 - Heuristic approach
